The three nonbonded (SA, HB, and CR) angles: a diagnostic for helical peptides. Current studies to determine the primary structure of a protein are usually based on the use of information from the sequence, such as whether there are a large number of basic (R) or acidic (D) residues, or whether there are few or many residues with small side chains. An alternative approach, however, is to utilize structural parameters such as the three dihedral angles (alpha, beta, gamma) for each amino acid residue. By limiting ourselves to helical peptides, in this study we have shown that information from the three dihedrals can be used to define a protein structure. We chose to look at glycine (Gly) residues because of their structural flexibility, and the use of two distinct Gly residues with either a cis or trans amide bond allows us to determine whether there are a large number of Gly residues or a small number of Gly residues. Furthermore, the presence of glycine in the trans form adds an important diagnostic feature, as the trans amide bond of the Gly residue prefers to be in a cis form. Thus, as the peptide is folded, the intermolecular bonds will prefer to be in a cis form at some position (alpha-r) but will favor a trans form at another position (gamma-t). The pair of angles which shows a preference for the cis form will indicate the location of the trans amide bond. We show that alpha-r and gamma-t are excellent diagnostic parameters for helical peptides with a Gly residue in the trans form. We studied the distribution of Gly dihedrals in a group of 100,000 synthetic oligomeric peptides. The three dihedrals (alpha-r, gamma-t, and gamma-r) of one of the Gly residues are plotted against the three dihedrals of the other Gly residues, and the three points are found on a cone, with a vertex at the origin and the axis formed by the 3-fold axes of the cone. In the trans form, the Gly dihedrals
